

Activity: Work with strings in Python

Activity: Work with strings in Python

Introduction

Security analysts work with a lot of string data. For example, some security analysts work on creating and updating IDs such as employee IDs and device IDs, which are commonly represented as strings. As another example, certain network activity will be stored as string data. Becoming comfortable working with strings in Python is essential for the work of a security analyst.

In this lab, you'll practice creating Python code and working with strings. You'll work with an employee ID, a device ID, and a URL, all represented as string data.

Tips for completing this lab

-
-
-
-
-

Scenario

You're working as a security analyst, and you are responsible for writing programs in Python to automate updating employee IDs, extracting characters from a device ID, and extracting components from a URL.

Task 1

In your organization, employee IDs are currently either four digits or five digits in length. In this task, you're given a four-digit numeric employee ID stored in a variable called `employee_id`. Convert this to a string format and store the result in the same variable. Later, you'll update this employee ID string so that it complies with a new standardized format.

Complete the following code. Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [1]:

```
# Assign `employee_id` to a four digit number as an initial value
```

```
employee_id = 4186
```

```
# Display the data type of `employee_id`
```

```
print(type(employee_id))

# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Display the data type of `employee_id` now

print(type(employee_id))
```

```
<class 'int'>
<class 'str'>
```

Hint 1

Use the `str()` function in Python to convert the initial value of the `employee_id` variable into a string.

Hint 2

Pass `employee_id` into the `str()` function.

Question 1

What do you observe about the data type of `employee_id` the first time it's displayed?

What do you observe about the data type of `employee_id` the second time it's displayed (after the variable is reassigned)?

First data type is integer and the second data type is string.

Task 2

Imagine that you have just been informed of a new criteria for employee IDs. They must all be five digits long for standardization purposes.

In this task, you will write a conditional statement that displays a message if the length of the employee ID is less than five digits.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [7]:

```
# Assign `employee_id` to a four digit number as an initial value

employee_id = 4186
```

```
# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Conditional statement that displays a message if the length of
`employee_id` is less than five digits

if len(employee_id) < 5:
    print("This employee ID has less than five digits. It does not meet length requirements.")
```

This employee ID has less than five digits. It does not meet length requirements.

Hint 1

The `len()` function in Python can be used to get the length of `employee_id`.

Hint 2

Start the conditional statement with the `if` keyword.

Hint 3

To write the condition in the conditional statement, use the `<` comparison operator to check whether the length of `employee_id` is less than `5`. Make sure to place the condition between the `if` and the `:`.

Task 3

In this task, you'll build upon the previous code. If an employee ID is only four digits, you'll use concatenation to create a five-digit employee ID number.

Concatenation is a process that allows you to merge strings together. The addition operator (`+`) in Python allows you to concatenate two strings.

Write an `if` statement that evaluates whether the length of `employee_id` is less than `5`. When the condition evaluates to `True`, reassign `employee_id` by concatenating `"E"` in front of the four-digit employee ID to create a five character employee ID. Then, display `employee_id` again. Be sure to replace each `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [10]:

```
# Assign `employee_id` to a four digit number as an initial value

employee_id = 4186
```

```

# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Display the `employee_id` as it currently stands

print(employee_id)

# Conditional statement that updates the `employee_id` if its length is less
than 5 digits

if len(employee_id) < 5:
    employee_id = "E" + employee_id

# Display the `employee_id` after the update

print(employee_id)

```

```

4186
E4186

```

Hint 1

Hint 2

Hint 3

Task 4

Now you'll move on to the next part of your task. Imagine that the characters in a device ID convey technical information about the device. You'll need to extract characters in specific positions from the device ID. Start off by extracting the fourth character.

The variable `device_id` represents a device ID containing alphanumeric characters; it's already stored as a string.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [14]:

```

# Assign `device_id` to a string that contains alphanumeric characters

device_id = "r262c36"

# Extract the fourth character in `device_id` and display it

```

```
print(device_id[3])
```

2

Hint 1

Use a pair of square brackets, passing in the appropriate index value, in order to extract the fourth character in `device_id`.

Hint 2

In Python, index values start at 0.

Hint 3

Given that index values start at 0 in Python, an index value of 3 corresponds to the fourth character in a sequence.

Task 5

Now you will also need to extract the first through the third characters in the device ID. So take a slice of the device ID. You can achieve this using bracket notation in Python. Then, display the slice to examine the result.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

```
In [15]:  
# Assign `device_id` to a string that contains alphanumeric characters  
  
device_id = "r262c36"  
  
# Extract the first through the third characters in `device_id` and display  
# the result  
  
print(device_id[0:3])
```

r26

Hint 1

Use a pair of square brackets, passing in the appropriate index values, in order to extract the first through the third characters in `device_id`.

Inside the square brackets, use a `:` to separate the first index value (the starting index value) and second index value (ending index value).

Hint 2

Keep in mind that the second index value passed into bracket notation is exclusive. In other words, the index value passed into the square brackets after the `:` is not included when the string is sliced. The resulting slice will not include the character at that index.

Hint 3

Recall that the second index value passed into bracket notation is exclusive and indexing in Python starts at `0`. The first index value should be `0` and the second index value should be `3`, in order to extract the first through the third characters in `device_id`.

Task 6

You'll now proceed to the last part of your task. This involves extracting components of a URL.

You'll work with string indices to display various components of a URL that's stored in the URL variable. First, you'll extract and display the protocol of the URL and the `://` characters that follow it using string slicing. Consider that the protocol is in the secure format of `https` when determining the indices for your slice.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [17]:

```
# Assign `url` to a specific URL
```

```
url = "https://exampleURL1.com"
```

```
# Extract the protocol of `url` along with the syntax following it, display the result
```

```
print(url[0:8])
```

```
https://
```

Hint 1

Note that `https://` is eight characters long.

Hint 2

Use a pair of square brackets to slice the string stored in `url`, passing in two index values separated by `:`. Keep in mind that the second index value is exclusive and that indexing in Python starts at `0`.

Hint 3

Use the `print()` function to display the slice.

Task 7

Later in this lab, you'll extract the domain extension. To prepare for this, use the `.index()` method to identify the index where the domain extension `.com` is located in the given URL.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [25]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Display the index where the domain extension ".com" is located in `url`

print(url.index(".com"))
```

19

Hint 1

Apply the `.index()` method to `url` in order to get the appropriate index. The `.index()` method takes in a substring, and if that substring is located in the original string, it returns the index where that substring starts to occur in the original string.

Hint 2

Call `url.index()`, and inside the parentheses, pass in the targeted domain extension as a string.

Task 8

It's a good idea to save important data in variables when programming. This allows for quick and easy tracking and reuse of information.

Store the output of the `.index()` method in a variable called `ind`, which is short for index. This index represents the position where the domain extension `".com"` starts in the `url`. Be sure to

replace the `### YOUR CODE HERE ###` with your own code before you run the following cell. Note that running this cell will not produce an output.

In [27]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")
```

Hint 1

To assign the extracted index to the `ind` variable, use the `.index()` method to the right of the `=` assignment operator.

Hint 2

Call `url.index()`, and inside the parentheses, pass in the targeted domain extension as a string. Be sure to place this to the right of the `=` assignment operator, so that the result is assigned to `ind`.

Task 9

You can use string slicing to also extract the domain extension of a URL. To do so, you can create a slice. The starting index should be the `ind` variable. This contains the index where the domain extension begins. The ending index should be `ind + 4` (since `".com"` is four characters long). Sometimes, like in this situation, it's easier to express the ending index in relation to the starting index. Examine the following code, run it as is, and observe the output.

In [28]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")

# Extract the domain extension in `url` and display it

print(url[ind:ind+4])
```

.com

Question 2

What does this code output and why?

This code outputs ".com". The reason being we used ind variable to store the domain and by slicing ind+4 it displays ".com"

Task 10

Finally, extract the website name from the given URL using string slicing and the ind variable that you defined earlier. In the given URL, the website name is "exampleURL1". Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [32]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")

# Extract the website name in `url` and display it

print(url[8:19])
```

exampleURL1

Hint 1

In order to extract the website name in the given URL, use a pair of square brackets to create a slice of url, passing in a start index and an ending index, separating the two with :.

Hint 2

The starting index should be set to 8, since this is the position after the protocol and the :// syntax ends and where the website name begins. The ending index should be set to the position where the .com domain name begins.

Conclusion

****What are your key takeaways from this lab?****

String functions and methods are really helpful in retrieving meaningful data

String index method helps us identify the numerical location of the character within the string

String Concatenation helps us combine strings

len() helps in finding the length of the string

slices help in extracting a piece of string data

Exemplar: Work with strings in Python

Introduction

Security analysts work with a lot of string data. For example, some security analysts work on creating and updating IDs such as employee IDs and device IDs, which are commonly represented as strings. As another example, certain network activity will be stored as string data. Becoming comfortable working with strings in Python is essential for the work of a security analyst.

In this lab, you'll practice creating Python code and working with strings. You'll work with an employee ID, a device ID, and a URL, all represented as string data.

Tips for completing this lab

-
-
-
-
-

Scenario

You're working as a security analyst, and you are responsible for writing programs in Python to automate updating employee IDs, extracting characters from a device ID, and extracting components from a URL.

Task 1

In your organization, employee IDs are currently either four digits or five digits in length. In this task, you're given a four-digit numeric employee ID stored in a variable called `employee_id`. Convert this to a string format and store the result in the same variable. Later, you'll update this employee ID string so that it complies with a new standardized format.

Complete the following code. Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [1]:

```
# Assign `employee_id` to a four digit number as an initial value

employee_id = 4186

# Display the data type of `employee_id`

print(type(employee_id))

# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Display the data type of `employee_id` now

print(type(employee_id))

<class 'int'>
<class 'str'>
```

Hint 1

Hint 2

Question 1

What do you observe about the data type of `employee_id` the first time it's displayed? What do you observe about the data type of `employee_id` the second time it's displayed (after the variable is reassigned)?

The first time it is displayed, the data type of `employee_id` is integer. The second time it is displayed (after the variable is reassigned), the data type of `employee_id` is string.

Task 2

Imagine that you have just been informed of a new criteria for employee IDs. They must all be five digits long for standardization purposes.

In this task, you will write a conditional statement that displays a message if the length of the employee ID is less than five digits.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [2]:

```

# Assign `employee_id` to a four digit number as an initial value

employee_id = 4186

# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Conditional statement that displays a message if the employee ID length is
less than 5 digits

if len(employee_id) < 5:
    print("This employee ID has less than five digits. It does not meet length
requirements.")

```

This employee ID has less than five digits. It does not meet length requirements.

Hint 1

Hint 2

Hint 3

Task 3

In this task, you'll build upon the previous code. If an employee ID is only four digits, you'll use concatenation to create a five-digit employee ID number.

Concatenation is a process that allows you to merge strings together. The addition operator (+) in Python allows you to concatenate two strings.

Write an `if` statement that evaluates whether the length of `employee_id` is less than 5. When the condition evaluates to `True`, reassign `employee_id` by concatenating "E" in front of the four-digit employee ID to create a five character employee ID. Then, display `employee_id` again. Be sure to replace each `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [2]:

```

# Assign `employee_id` to a four digit number as an initial value

employee_id = 4186

# Reassign `employee_id` to the same value but in the form of a string

employee_id = str(employee_id)

# Display the `employee_id` as it currently stands

```

```
print(employee_id)

# Conditional statement that updates the `employee_id` if its length is less
than 5 digits

if len(employee_id) < 5:
    employee_id = "E" + employee_id

# Display the `employee_id` after the update

print(employee_id)
```

```
4186
E4186
```

Hint 1

Hint 2

Hint 3

Task 4

Now you'll move on to the next part of your task. Imagine that the characters in a device ID convey technical information about the device. You'll need to extract characters in specific positions from the device ID. Start off by extracting the fourth character.

The variable `device_id` represents a device ID containing alphanumeric characters; it's already stored as a string.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [4]:

```
# Assign `device_id` to a string that contains alphanumeric characters

device_id = "r262c36"

# Extract the fourth character in `device_id` and display it

print(device_id[3])
```

```
2
```

Hint 1

Hint 2

Hint 3

Task 5

Now you will also need to extract the first through the third characters in the device ID. So take a slice of the device ID. You can achieve this using bracket notation in Python. Then, display the slice to examine the result.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [5]:

```
# Assign `device_id` to a string that contains alphanumeric characters
```

```
device_id = "r262c36"
```

```
# Extract the first through the third characters in `device_id` and display the result
```

```
device_id[0:3]
```

Out [5]:

```
'r26'
```

Hint 1

Hint 2

Hint 3

Task 6

You'll now proceed to the last part of your task. This involves extracting components of a URL.

You'll work with string indices to display various components of a URL that's stored in the URL variable. First, you'll extract and display the protocol of the URL and the `://` characters that follow it using string slicing. Consider that the protocol is in the secure format of `https` when determining the indices for your slice.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [6]:

```
# Assign `url` to a specific URL
```

```
url = "https://exampleURL1.com"
```

```
# Extract the protocol of `url` along with the syntax following it, display the result
```

```
print(url[0:8])
```

```
https://
```

Hint 1

Hint 2

Hint 3

Task 7

Later in this lab, you'll extract the domain extension. To prepare for this, use the `.index()` method to identify the index where the domain extension `.com` is located in the given URL.

Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [7]:

```
# Assign `url` to a specific URL
```

```
url = "https://exampleURL1.com"
```

```
# Display the index where the domain extension ".com" is located in `url`
```

```
print(url.index(".com"))
```

```
19
```

Hint 1

Hint 2

Task 8

It's a good idea to save important data in variables when programming. This allows for quick and easy tracking and reuse of information.

Store the output of the `.index()` method in a variable called `ind`, which is short for index. This index represents the position where the domain extension `.com` starts in the `url`. Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell. Note that running this cell will not produce an output.

In [8]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")
```

Hint 1

Hint 2

Task 9

You can use string slicing to also extract the domain extension of a URL. To do so, you can create a slice. The starting index should be the `ind` variable. This contains the index where the domain extension begins. The ending index should be `ind + 4` (since `".com"` is four characters long). Sometimes, like in this situation, it's easier to express the ending index in relation to the starting index. Examine the following code, run it as is, and observe the output.

In [9]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")

# Extract the domain extension in `url` and display it

print(url[ind:ind+4])

.com
```

Question 2

What does this code output and why?

This code outputs the domain name `.com` by first saving the starting position of the domain name in the `ind` variable and then extracting 4 consecutive characters from `url` starting from the saved position.

Task 10

Finally, extract the website name from the given URL using string slicing and the `ind` variable that you defined earlier. In the given URL, the website name is `"exampleURL1"`. Be sure to replace the `### YOUR CODE HERE ###` with your own code before you run the following cell.

In [10]:

```
# Assign `url` to a specific URL

url = "https://exampleURL1.com"

# Assign `ind` to the output of applying `.index()` to `url` in order to
extract the starting index of ".com" in `url`

ind = url.index(".com")

# Extract the website name in `url` and display it

print(url[8:ind])
```

exampleURL1

Hint 1

Hint 2

Conclusion

What are your key takeaways from this lab?

- Strings are instrumental in storing important, security-related data, such as device IDs and URLs.
- String concatenation allows you to easily combine information in a string with the information stored in another string.
- String slicing is a powerful technique that enables you to extract any subsection of a string.
- Python has many functions and methods that help analysts work with string values, as well as data that they want to convert to string format.
 - The `type()` function returns the data type of its input.
 - The `str()` function converts the input object into a string. For example, when called on an integer, `str()` returns that integer value converted to a string.
 - The `len()` function returns the number of elements in an object. When called on a string, `len()` returns the number of characters in that string.
 - The `.index()` method finds the first occurrence of the input in a string and returns its location. It provides the index where the substring begins.
